Abstract. Computing a better crustal thickness model is still a necessary improvement in Antarctica. In this remote continent where almost all the bedrock is covered by the ice sheet, seismic investigations do not reach a sufficient spatial resolution for geological and geophysical purposes. Here, we present a global map of Antarctic crustal thickness computed from space gravity observations. The DIR5 gravity field model, built from GOCE and GRACE gravimetric data, is inverted with the Parker–Oldenburg's iterative algorithm. The BEDMAP products are used to estimate the gravity effect of the ice and the rocky surface. Our result is compared to crustal thickness calculated from seismological studies, CRUST1.0 and AN1 models. Although CRUST1.0 model shows a very good agreement with ours, its spatial resolution is larger than the one we obtain with gravimetric data. Finally, we compute a model where the crust/mantle density contrast is adjusted to fit the Moho depth from CRUST1.0 model. In East Antarctica, the resulting density contrast clearly shows higher values than in West Antarctica.

1. Introduction

The surface topography of Antarctica has already been determined precisely by the various altimetric missions: ERS1/2, EnviSat, ICESat or Cryosat-2 (Zwally et al., 2002; Rémy and Parouty, 2009; Helm et al., 2014) and more recently by the SARAL or Sentinel-3 satellites (Verron et al., 2015). Glaciologists could track temporal variations of the surface and estimate the volume changes of the whole ice sheet (Zwally et al., 2011; Flament and Rémy, 2012; McMillan et al., 2014). For the last 15 years, space gravimetry has been providing to the scientific community a complementary tool to observe and follow the distribution of masses...
inside the Earth. The main advantage is that the gravity observations have a homogeneous accuracy whatever the region of interest, i.e. over mountains, oceans or whole continents alike. Satellites are the only way to have information where gravimetric ground data are lacking. Such observations have provided to the glaciologists the thickness of the ice cover and the temporal tracking of the ice sheet. Launched in 2002, the GRACE mission provides monthly or 10 days temporal grids (Lemoine et al., 2007; Foerste et al., 2008; Landerer and Swenson, 2012). It allows the computation of mass balance, annual or seasonal cycles (Ramillien et al., 2006; Llubes et al., 2007; Peng et al., 2016; Ramillien et al., 2006; Williams et al., 2014). In addition, temporal variations in the gravity field can be used for climate or global change purposes as a contribution to the sea level rise equation (Jacob et al., 2012). Jointly with altimetric data, space gravimetry is used to separate snow and ice contributions (Memin et al., 2014).

Glaciological studies also need the spatial ice thickness patterns, if only to simply estimate the volume of the polar ice sheet. When modelling the ice dynamics, a crucial parameter is the ice thickness and all simulations of ice thinning in response to climate forcing include this parameter as a main factor (Ritz et al., 2001). For this reason, the community made a real effort to collect and combine all the available sources of information to compute the most complete maps over Antarctica, named BEDMAP (Lythe et al., 2001). The BEDMAP consortium provides grids of ice-surface elevation, ice thickness and bedrock subglacial topography. However, under the ice surface that covers nearly 99% of Antarctica, ice thickness is still unknown in areas without any ground data. In fact, the unobserved areas represent more than 360000 km², and the map displays very large regions without any information. These areas without observations are too large to be interpolated.

Satellite gravimetry could fill-in the missing ground data, and can be used to estimate the ice thickness (Fretwell et al., 2013).

Furthermore, as gravimetric observations are influenced by all mass distributions, they can also reveal deeper information, such as the Moho depth. An estimate of Antarctica's crustal thickness would be useful to geological studies, and help to understand the formation of the continent. Actually, Antarctica is still the least known continental area. The scientific community needs improvements of the available crust models, at a continental scale but also at a more detailed scale. Geological studies, especially observations at the bedrock surface, would gain to know more about the crustal structure. In the past, some studies computed the crustal thickness patterns from previous space gravimetric missions – CHAMP, launched in 2000 (Llubes et al.,
2003), and GRACE (Block et al., 2009; Llubes et al., 2003). GOCE, a third satellite mission dedicated to observe the gravity field with a higher spatial resolution and a high accuracy, could provide more detailed maps of the Moho depth. The other way to obtain information about the Moho boundary is to look at seismology data. Some studies already used seismological data to constrain the computation of crustal thickness from gravimetric data (O’Donnell and Nyblade, 2014). But the comparison is limited to a few locations and it is difficult to get a good correlation coefficient between the crustal thicknesses obtained from the two types of data. Actually, only space gravimetry can cover the Antarctica continent with a complete and dense dataset.

The aim of this paper is to provide a map of crustal thickness variations of the Antarctica continent based on the most recent combined space gravity field, named DIR5 (Bruinsma et al., 2014). We postulate that subsurface contributions can be properly removed using the pre-GOCE BEDMAP grids to compute the Moho topography. Then we discuss our choices replacing the gravity field by the only GRACE and LAGEOS model EIGEN-GRGS.RL02bis (Bruinsma et al., 2010), or preferring Bedmap2 products. Finally, we compare our crustal thickness map to global models issued from seismological data: CRUST1.0 (Laske et al., 2013) and AN1 (An et al., 2015). The CRUST1.0 model allowed us to adjust the density of the crust in Antarctica and to map its variations.

2. Datasets

2.1 Gravity field solutions

European Space Agency’s (ESA) first Earth Explorer mission GOCE, Gravity field and steady state Ocean Circulation Explorer (Drinkwater et al., 2003), was launched on 17 March 2009 and reentered the atmosphere on 11 November 2013. The Science Mission lasted from 1 November 2009 to 22 October 2013. GOCE was dedicated to mapping the static gravity field with a high spatial resolution of 100 km, which required measuring from a low altitude of about 250 km.

Data from GOCE (gravity gradients), LAGEOS 1/2 and GRACE were combined in the latest release DIR5 (Bruinsma et al., 2014) in order to obtain a high-accuracy gravity field model over the entire spectral range.
This model is provided in terms of spherical harmonics up to degree 300, but was used in this study to degree 260, i.e. 77 km of spatial resolution.

It is important to note that, due to the inclination of GOCE satellite, the polar regions cannot be observed. In the case of Antarctica, GOCE can only cover the continent up to 83.3°S in latitude, and that the combined model DIR5 includes GRACE satellite data at higher latitudes.

For our study, we computed a regular 0.25°x0.25° spatial grid of free air gravity anomalies over the Antarctica continent with the DIR5 model, which is displayed in Figure 1. The gravity anomalies have amplitudes between -120 and 111 mGal (more statistical data are provided in Table 1).

In this paper we have also used the only GRACE and LAGEOS mean gravity field model EIGEN-GRGS.RL02bis (Bruinsma et al., 2010). This gravity field model is also provided in terms of spherical harmonics up to degree 160 i.e 125 km of spatial resolution.

2.2 BEDMAP models.

Bedmap2 products (Fretwell et al., 2013) consist of grids describing surface elevation, ice-thickness, the seafloor and subglacial bed elevation of the Antarctic south of 60°S. These products were made incorporating all available geophysical data. More details of Antarctica subglacial landscape are visible in these products than in the previous BEDMAP model (Lythe et al., 2001) and the improved data coverage reveals the full details of mountain ranges, valleys, basins and troughs. Each dataset is provided in Antarctic Polar Stereographic projection, latitude of true scale 71 degrees south, datum WGS84. All heights are in meters relative to mean sea level as defined by the EIGEN-GL04C geoid (Foerste et al., 2008). The ice thickness, bedrock and surface elevation grids are provided at uniform 1-km spacing.

In this analysis GOCE data are used to estimate ice thickness over the regions where observations are lacking. We use ice thickness given in the previous release, BEDMAP, which did not include GOCE data. With the aim to represent the same range of wavelengths as the gravimetric anomalies, we analyse the difference between both ice thickness estimates after filtering it to the maximum spatial resolution of GOCE, in this study 77 km. We notice that this difference is largest at short and medium wavelengths (see Figure 2). The maximum is 1628 m, the minimum is -896 m, and the mean difference is 19 m. The new Bedmap2 seems to improve the
estimate of the ice thickness all over the continent. A more complete comparison between both products is given by (Hirt, 2014).

We select the datasets between BEDMAP and Bedmap2 so that Antarctica models and gravity observations remain independent. Finally, in order to have a consistent bedrock topography, it is calculated as the difference between the most precise topography from Bedmap2 and the ice thickness from BEDMAP.

2.3 Crustal thickness models from seismology

CRUST1.0 is a 1-by-1 degree global crustal model (Laske et al., 2013). This model is an upgrade of the previous model CRUST1.0 including crustal thickness from new active seismic observations. In areas where there is a lack of seismic observations, crustal thickness is constrained by gravity observations using maps from the British Antarctic Survey (Laske private communication). Baranov and Morelli (2013) in a Moho depth map compiling geophysical data pointed out disagreements with CRUST1.0. The new version of this crust model may solve the problem.

Recently, another crustal model has been proposed by a Chinese team (An et al., 2015). This model is based exclusively on seismic observations. This will provide us with an independent model for comparison with our result from gravity data. In Antarctica, there are very few seismological observations compared to gravity data, for example in areas of East Antarctica such as QML (Queen Maud Land) and AGV (George V land) (see the station distribution in Kanao et al. 2013 figure 1 or in An et al. 2015 figure 4). The comparison between AN1 and CRUST1.0 models reveals large differences. As seen in Figure 3, from -26 to +19 km, AN1 has higher values, mainly localized in the East Antarctic craton. West Antarctica is much thinner in CRUST1.0 than in the AN1 model. The roughness in the AN1 model around the coast line is related to its resolution. Including gravimetric observations (land and/or satellite) as constraints of the seismological model allows to improve the spatial resolution.

In order to estimate the gravity anomalies mainly due to crustal thickness variations, we compute, with Parker's method (Parker, 1973), the gravitational terrain effects using BEDMAP ice thickness, and Bedmap2 sea depth and surface topography. In our case, Parker's approach is the most adequate because of the improved spatial resolution obtained using GOCE observations. When the spatial resolution is larger than 300 km, we cannot use a simple Bouguer approach to estimate gravity effects. Parker proposed to use Fourier transforms to calculate the gravitational effect of an uneven, non-uniform layer of material.

To simplify the computations, the rock equivalent topography is calculated as (Balmino et al., 2012; Hirt, 2014):

$$ H_r = H_b + \frac{\rho_e}{\rho_r} H_o + \frac{\rho_l}{\rho_r} H_i $$ (1)

Where $H_r$ is the rock equivalent topography, $H_b$ the bedrock topography, $H_o$ the ocean depth, $H_i$ the ice thickness, $\rho_r$ the rock density (2.670), $\rho_o$ the sea water density (1.03), and $\rho_i$ the ice density (0.917).

Using Parker’s method in a MATLAB function developed by Simmons (http://geoweb.princeton.edu/people/simons/software.html), we estimate the terrain gravitational effects by considering only one interface of constant density $\rho_r$ with a topography given by eq. (1). The resulting gravitational effect filtered to GOCE spatial resolution on the pole, (i.e., around 77 km) is shown in Figure 4a.

The difference between the free air anomalies derived from GOCE and the terrain effects gives the Bouguer anomaly (Fig. 4b), which is essentially due to crustal thickness variations. However, the anomaly also includes the effect of the errors in layer’s thickness given by BEDMAP and Bedmap2 models, especially at long spatial wavelengths, so that geophysical signal from the upper mantle may not be revealed by this study.

The statistical information on GOCE free air anomalies, gravitational terrain effects and Bouguer anomalies are given in Table 1. The free air gravity anomalies obtained by GOCE show variations between -120 and 110 mGal. The Bouguer anomalies vary between -250 and 360 mGal, with a very different pattern. On Figure 4b, there is a large discrepancy between the eastern part and the western part of the continent, which reflects the geological structure and history of Antarctica. There are also a lot of details at higher resolution revealed by the low degrees of spherical harmonics in GOCE gravity field. The inversion of these Bouguer anomalies will help us better understand the crustal structure.
4. **Inverse problem: crustal thickness estimation.**

To obtain crustal thickness variations from our estimated Bouguer anomalies, we resolve the inverse problem using the Parker–Oldenburg iterative algorithm. To this purpose we use the 3dinver MATLAB function proposed by (Gómez-Ortiz and Agarwal, 2005), which allows the computation of a 3D topography of a constant density layer to fit the Bouguer anomaly.

To solve the inverse problem, we assume the full crustal isostatic compensation of topography, we must choose as input the density contrast and the mean depth of the layer. Considering that the mantle density is 3.3, we choose a density contrast of 0.63 to be consistent with our gravity terrain effects computation (rock density 2.670). According to previous studies (Block et al., 2009; Ritzwoller et al., 2001), the mean Moho depth is about 40 km in West Antarctica and about 30 km in East Antarctica. We choose the average value, 35 km, as mean depth for the whole continent for the starting computation.

A higher-cut filter is required to ensure convergence of the inverse problem (see section 2, Gómez-Ortiz and Agarwal, 2005). In our case this filter restricts frequency contents between wavelengths of 77 km and 100 km.

Additionally, in order to provide information about the accuracy of the inversion, the 3dinver program computes the residual between the gravity effect of the output layer’s topography and the observed Bouguer anomalies used as input. The RMS is only about 5 mGal indicating a satisfactory fit.

The computed crustal thickness is shown in Figure 5. Spatial variations from 29.7 to 51 km can be observed, with a mean thickness value of 41 km (see Table 1). The latter is slightly larger than the mean value of both seismological models, because for these models we included some thin oceanic crust in the estimation of the mean thickness. The AN1 model has a higher standard deviation compared to the others. This may come from the high noise level observed in a few geographical areas.

As it was already confirmed in several previous studies, Antarctica is separated into two unequal parts, testifying to the complex formation of this continent. The TransAntarctic Mountains (TAM, Figure 5) delimit the border between the thick crust in East Antarctica (EA) and the thin crust in West Antarctica (WA). The latter is formed by a complex assemblage of geological structures, still under study (Lindow et al., 2016;
The Peninsula (P) and the Marie Byrd Land (MBL) have the highest crustal thickness of this continental part, reaching 45 km in some places. The crust in the rest of the area is mainly thinner than 35 km. East Antarctica’s structure and history are better understood. Geological, geochemical, petrological and isotopic studies (Mikhal’sky, 2008; Dasgupta et al., 2001) suggested that East Antarctica is an old craton resulting from several tectonic events. Successive deformation phases remodeled its crust over time. For example, in the Dronning Maud Land, age data reveal primary Grenvillian rocks which had been intruded by Pan-African igneous episodes (Paech, 2001). Seismic imaging contributes to the understanding of the evolution of this region (Kanao et al., 2011) and to the mapping of variations in the Moho depth. (Bayer et al., 2009) observed a crustal thickening from coast to inland, between 40 km and 51 km. Our gravimetric study confirms this tendency (Figure 5), related to the continuing thick crust in the central part of East Antarctica, whereas the adjacent region in the west side is thinner. Also, the Lambert Rift (LR) clearly appears in our crustal model (Figure 5), and the enigmatic structure of the Gamburtsev Mountains (GSM) seems to be independent from the surrounding geological pattern. As the origin of these subglacial mountains was poorly known, a specific seismic survey was performed (Wolovick et al., 2009). Now, with our regional map derived from GOCE data, it is possible to follow specific geological structures over the whole continent. Our results can also be useful to develop and analyze an isostatic model to further interpret the topographic structures (O’Donnell and Nyblade, 2014).

5. Discussion.

5.1 About our choices in the computation of the crustal model

5.1.1 BEDMAP or Bedmap2

When computing the direct gravitational effect, we had to choose a model for all contributing layers. The best grids for the ice thickness – and so for the bedrock elevation – are provided by BEDMAP in the most complete data compilation available. The new version of these products, Bedmap2, also includes (satellite gravity) data from GRACE and GOCE. So we preferred to use the prior version BEDMAP for the ice thickness variations to have strictly independent grids, which allows us to estimate the gravitational effect of the ice. But Bedmap2 incorporates two orders of magnitude more data than BEDMAP, it has a better spatial resolution, coverage and precision at any wavelength. It is interesting to estimate the impact of Bedmap2 in our crustal inversion.
We did the same process as the previous calculation, up to the computation of the crustal thickness, but using ice thickness from Bedmap2. The differences between both solutions span from -3.7 to +12.2 km, but the standard deviation is only 1.2 km (see Table 1 for these statistical data). The higher values are not always located in the areas completed by satellite gravity in Bedmap2, because the large set of new data included during the computation really improved the model. In Figure 6a, the pink line shows the areas for which no ground data were available within at least 50 km. We can trust that the new version of BEDMAP is closer to reality outside the pink line limit, and our direct estimation is more accurate within this limit. Some geological details appear in the crust variations estimate when computed with Bedmap2 ice thickness. The improvement of this version is important, even when dealing with the base of the continental crust. It would be interesting to have a version of this product that does not depend on satellite gravity data.

5.1.2 Improvement from GOCE compared to GRACE observations

GOCE is the latest of three space missions dedicated to gravity field modeling. In a lower altitude orbit, equipped with a gradiometer, it measured smaller details of the gravity field. The GRACE mission was launched at a higher altitude, mainly to observe the temporal variations. But thanks to its long and still ongoing mission, it is also possible to compute an accurate geoid. The spatial resolution in GRACE-derived geoid is less than the that in the geoid obtained with GOCE, but we could evaluate the differences in our crust estimate using one or the other. Additionally, we hoped to see crustal details in the 77 – 120 km wavelength band. It should be noted that the GOCE geoid grid is a combined solution incorporating GRACE data.

The difference between both crustal thicknesses, from only GRACE model EIGEN-GRGS.RL02bis and from GOCE DIR5 gravity anomalies, clearly shows a high frequency signal, corresponding to the contribution of GOCE at small spatial scales. The discrepancies range between ±7 km, emerging from the ambient noise level. They are mainly located over the Transantarctic Mountains (TAM), the peninsula (P), and in the western part of the continent. In East Antarctica (EA), both models are really closed. The differences do not exceed 2 km, except in the Lambert Rift (LR) – see Figure 5 for location of TAM, P, EA and LR. The new GOCE DIR5 version thus provides interesting details for geological interpretation and the knowledge of Antarctica structure.
5.2 Comparison with models using seismology observations

5.2.1 The entire maps

We already compared both models issued from the seismology community (see Sect. 2.3). Clearly, CRUST1.0 appears to be closer to our result. We computed the difference between them and plotted the corresponding map (Figure 6b). Doing the same with the AN1 model will give differences identical to those between CRUST1.0 and AN1 because they dominate: the latter model is far from the two others. The crustal thickness computed in this paper is on average 1.2 km higher than for the CRUST1.0 model. The larger discrepancies are located all around the Antarctica continent, because the two coast limits can differ. We also note that our crust estimate is thinner in the TransAntarctic Mountains, in some regions of West Antarctica and in the center of East Antarctica. CRUST1.0 has smaller amplitude variations, the lowest and highest values are reached by our model (see Table 1 for statistical results).

5.2.2 Spatial analysis of crustal models

Spectral study

We computed the power spectral densities of the crustal thickness. They are shown in Figure 7.a from 0 to 1000 km for crustal thickness obtained from GOCE data, from GRACE data, or given by the CRUST1.0 and AN1 models. There are very few differences at any wavelength between thickness from GOCE DIR5 model and the one from only GRACE EIGEN-GRGS.RL02bis model. This confirms the remark made in Sect. 5.1.2 about their very small spatial differences. Because GOCE DIR5 grids also incorporate GRACE data, they are naturally close to one another, except when looking at wavelengths smaller than 120 km, where the differences are larger. The additional improvement by using GOCE data at small wavelengths is not really clear.

The comparison of gravity-derived and seismological models shows a clear discrepancy between them even if the large-scale tendency is the same. The spectral densities show more energy for crustal thickness derived from gravity observations (Figure 7.a).
In fact, we worked with the complete gravitational signal to inverse the crustal thickness. This signal includes effects from the underlying mantle, which are not taken into account in our interpretation. These effects likely have a long-wavelength pattern, but there is no specific signal in the spectral curve. Seismological models are not affected by these effects and they share the same behavior at short wavelength. Therefore, there is probably no significant mantellic disturbance in our crustal thickness estimate. Anyway, it is not possible to isolate and correct it during the computation process.

Profiles tracking

To compare the crustal models more easily, four profiles have been extracted along geographical paths (Figure 7b), oriented S-N (c), W-E (d), NW-SE (e) and SW-NE (f), respectively. Firstly, the main differences appear over the oceans and over the two ice shelves, because our inversion method is not adapted to these regions (we cut a part of the plots on Figure 7). Secondly, there are large discrepancies near the coast limit, which is not the same for all models.

On the continent, CRUST1.0 is very close to our results, but it always has smaller thickness values. But as we had to choose a mean depth to compute the Moho’s spatial variations, this difference is not relevant. Looking at the four plots, we see a higher discrepancy in the North and West parts of the continent. For example, in Dronning Maud Land, CRUST1.0 gives a thinner crust than our models. Smaller scale variations are visible in the GOCE DIR5 and GRACE EIGEN-GRGS.RL02bis profiles, while CRUST1.0 is smoother.

Clearly, AN1 is very different from the three others. It shows less spatial details, with a more constant profile along west Antarctica. In the Gamburtsev Subglacial Mountains region, the model reaches its maximum with a sudden thickening up to 65 km, over a very restrictive area (Figure 7.d). No other model shows such a local crustal thickening.

Comparison with seismic receiver functions

To complete the confrontation with seismic crustal thicknesses, we compare our results to those from receiver functions. We use the Antarctic Moho compilation given by An (Figure 4 and Table S1 from An et al., 2015),
who selected a list of stations to evaluate the quality of Moho depth (more details and sources can be found in An et al., 2015). On Figure 8, we plot the differences between the crustal thickness from GOCE and the value derived from receiver functions. Roughly, we obtain the same discrepancies as those observed with the profiles on Figure 7. There is a disagreement near the Gamburtsev Subglacial Mountains region (GSM). Seismic data show a thickening up to 60-65 km in this region, while gravity suggests a more regular crust with thicknesses under 50 km.

Conversely, in West Antarctica seismic studies find 20 to 30 km-thick crust, which is thinner than our crust estimate from space gravity (Figure 8). Using receiver functions from POLENET, Chaput et al. (2013) explain that this thin crust probably results from compensating mantle low density, especially across MBL dome (Marie Byrd Land). During our computation at continental scale, we had to postulate the full crustal isostatic compensation of topography. In regions with mantle compensation or with density variations, our results will differ from the real crustal thickness. Specific studies have to be performed in regions where these effects are suspected, based on seismic data but also on airborne (Scheinert and al., 2016) or ground gravity data, the latter having a better resolution, appropriate for local studies.

5.2.3 Density estimation

In our computation, we chose a 0.63 density contrast because it was consistent with previous studies and a very classical choice in such geological context. Recently, O’Donnell and Nyblade (2014) proposed a smaller contrast of 0.3 when they adjusted the crustal thickness based on gravimetric data to seismological results. Therefore, it was important to reconsider the density of the crust and the upper mantle in Antarctica. We decided to use a simple Bouguer formula to estimate the density contrast variations, assuming that the observed Bouguer anomalies are mainly due to density variations. The Bouguer anomaly map is filtered to 333 km, and we chose the CRUST1.0 model for the crustal thickness. The result is shown in Figure 9 and it represents the variations around the crust’s mean density value of 2.67 when mantle density is fixed at 3.3. We notice that the density is slightly smaller in the western part of the continent. Few spatial variations are visible on Figure 9. Density seems to be constant enough, from 2.72 to 2.8 in East Antarctica and from 2.62 to 2.75 in West Antarctica. Geological studies in this latter region indicate a complex assembly, made by
several tectonic plates, thinner and younger than the old eastern craton, explaining the density discrepancy. This is consistent with the results of (Tenzer and Bagherbandi, 2013), except in Marie Byrd Land where we found an increase of density not visible in their study. However, gravimetric observations do not need spatially-varying density to be interpreted. A constant density contrast is a good first hypothesis to compute the inversion of the Bouguer anomalies and obtain the crustal thickness.

6. Conclusion.

We provide a regional map of crustal thickness, covering the entire Antarctic continent. Thanks to the new GOCE gravity field model, a spatial resolution of 77 km is reached with almost the same accuracy anywhere. Compared to previous studies, smaller details appear on the map, and the noise level is lower because we used the latest available gravity grids which compile all GRACE and GOCE data. However, the ice thickness estimation remains a key parameter during the process. An improved ice thickness map, made from radar satellite observations and fully independent from gravity data, would benefit not only glaciological but also our crustal studies.

Currently, comparing our result to seismological models shows a fairly good agreement. Some studies already tried to use seismic observations to constrain the thickness derived from gravimetry, and seismological models begin to include gravimetric observations. Next, a joint inversion of seismological and gravimetric data, including data from satellite missions, will provide the next crustal model of Antarctica. All studies concern long spatial wavelengths, usually larger than ~100 km. Geophysical and geological studies need a higher spatial resolution to understand the crustal structure over more local regions. Antarctica is still the Earth’s place where the crust is least known. It will be a real challenge to improve the crustal model resolution even if only for specific areas. Maybe additional gravity campaigns or satellite missions will allow this progress.

Our computed crustal thickness models of Antarctica will be available on the International Gravimetric Bureau website (http://bgi.omp.obs-mip.fr/).

Acknowledgements
We thank G. Laske for the information she provided to us about CRUST1.0 model. We thanks Anne Briaïs who made very useful suggestions and the reviewers for their constructive comments. This work has been supported by University Paul Sabatier (Observatoire Midi-Pyrénées) and the French space agency CNES.

**Table 1:** Statistical data for maps used in this study. The three first rows are in mGal, and the others are in km. The * indicates the application of a 77km low-pass filter.
Figure 1. Free air anomalies in mGal from GOCE DIR5 solution.
Figure 2. Difference between ice thickness from Bedmap2 and BEDMAP (max: 1628 m, min: -896 m, mean: 19 m). This difference is filtered to the maximum spatial resolution of GOCE (77 km) to represent the range of wavelengths that are significant in our study.
Figure 3. Difference between crustal models AN1 and CRUST 1.0 based on seismological data. Units are km.
Figure 4.a) Gravitational terrain effect derived from BEDMAP ice thickness, sea and bedrock topography. Low pass filter of 77 km cut-off is applied. b) Bouguer anomalies estimated as the difference between GOCE observed free air anomalies and terrain effects. (in mGals)
Figure 5. Estimation of crustal thickness (in km) from GOCE gravity observations. Geographical locations mentioned in the text are: Dronning Maud Land (DML), Lambert Rift (LR), Gamburtsev Subglacial Mountains (GSM), TransAntarctic Mountains (TAM), Marie Byrd Land (MBL) and the Peninsula (P). The large TAM separate East Antarctica (EA) from West Antarctica (WA).
Figure 6. a) Differences between estimation of crustal thickness: results using BEDMAP minus results using Bedmap2. The pink line delimitates the zones where GOCE observations are used in Bedmap2. Units are km. b) Differences between the crust thickness computed from GOCE and the CRUST1.0 model. Units are km.
Figure 7. Spectral analysis crust thickness models (a), and their thickness variations over 4 profiles (shown with yellow lines in fig b). The Antarctica map is converted in a cartesian X-Y coordinate system. The profiles are c) parallel to Y, d) parallel to X, e) X=Y and f) X=-Y. The south pole is located at (0,0).
Figure 8. Differences between crustal thickness obtained in this study and those from the compilation of receiver functions selected by An (An et al., 2015). Units are km.
Figure 9. Density variations estimated from CRUST 1.0 crustal thickness variations.
